2.3. Establishing "Bone" Criteria

After narrowing down our list to 10 filaments with kinematic structure consistent with existing spiral arm models, we develop a set of criteria for an object to be called a "bone":

1. Largely continuous mid-infrared extinction feature
2. Parallel to the Galactic plane, to within 30°
3. Within 20 pc of the physical Galactic mid-plane, assuming a flat galaxy
4. Within 10 km s^{-1} of the global-log spiral fit to any Milky Way arm
5. No abrupt shifts in velocity (of more than 3 km s^{-1} per 10 pc) within extinction feature
6. Projected aspect ratio $\geq 50:1$.

Figure 7 The four stages of star formation. (a) Cores form within molecular clouds as magnetic and turbulent support is lost through ambipolar diffusion. (b) A protostar with a surrounding nebular disk forms at the center of a cloud core collapsing from inside-out. (c) A stellar wind breaks out along the rotational axis of the system, creating a bipolar flow. (d) The infall terminates, revealing a newly formed star with a circumstellar disk.

ABSTRACT

After studying how line width depends on spatial scale in low-mass star-forming regions, we propose that “dense cores” (Myers & Benson 1983) represent an inner scale of a self-similar process that characterizes larger scale molecular clouds.

FIG. 10.—An illustration of the transition to coherence. Color and shading schematically represent velocity and density in this figure. On large scales, material (labeled chaff) is distributed in a self-similar fashion, and its filling factor is low. On scales smaller than some fiducial radius, the filling factor of gas increases substantially, and a coherent dense core, which is not self-similar, is formed. Due to limitations in the authors' drawing ability, the figure emphasizes a particular size scale in the chaff, which should actually exhibit self-similar structure on all scales ranging from the size of an entire molecular cloud complex down to a coherent core.

— In the localized regions, the concentration of acceleration can lead to local collapse. The local collapse can occur in a timescale that is much shorter (e.g. 10^6 yr) than the dynamical timescale of the cloud.

However, a complete picture of gas evolution is yet to be achieved since we need to fully understand the interplay between magnetic field, turbulence and gravity in these these regions. There are ample observational evidences that magnetic fields are important in star-forming regions (Li et al. 2014). Remarkably-ordered magnetic fields have been

THE SKELETON OF THE MILKY WAY

CATHERINE ZUCKER¹, CARA BATTERSBY², AND ALYSSA GOODMAN²

¹Astronomy Department, University of Virginia, Charlottesville, VA 22904, USA; catherine.zucker@cfa.harvard.edu

²Harvard-Smithsonian Center for Astrophysics, Cambridge, MA 02138, USA

Received 2015 June 27; accepted 2015 September 21; published 2015 MM DD

ABSTRACT

Recently, Goodman et al. argued that the very long, very thin infrared dark cloud “Nessie” lies directly in the Galactic midplane and runs along the Scutum–Centaurus Arm in position–position–velocity (p – p – v) space as traced by lower-density CO and higher-density NH₃ gas. Nessie was presented as the first “bone” of the Milky Way, an extraordinarily long, thin, high-contrast filament that can be used to map our Galaxy’s “skeleton.” Here we present evidence for additional bones in the Milky Way, arguing that Nessie is not a curiosity but one of several filaments that could potentially trace Galactic structure. Our 10 bone candidates are all long, filamentary, mid-infrared extinction features that lie parallel to, and no more than 20 pc from, the physical Galactic mid-plane. We use CO, N₂H⁺, HCO⁺, and NH₃ radial velocity data to establish the three-dimensional location of the candidates in p – p – v space. Of the 10 candidates, 6 also have a projected aspect ratio of $\geq 50:1$; run along, or extremely close to, the Scutum–Centaurus Arm in p – p – v space; and exhibit no abrupt shifts in velocity. The evidence presented here suggests that these candidates mark the locations of significant spiral features, with the bone called filament 5 (“BC_18.88-0.09”) being a close analog to Nessie in the northern sky. As molecular spectral-line and extinction maps cover more of the sky at increasing resolution and sensitivity, it should be possible to find more bones in future studies.

Key words: Galaxy: kinematics and dynamics – Galaxy: structure – ISM: clouds

2.3. Establishing “Bone” Criteria

After narrowing down our list to 10 filaments with kinematic structure consistent with existing spiral arm models, we develop a set of criteria for an object to be called a “bone”:

1. Largely continuous mid-infrared extinction feature
2. Parallel to the Galactic plane, to within 30°
3. Within 20 pc of the physical Galactic mid-plane, assuming a flat galaxy
4. Within 10 km s⁻¹ of the global-log spiral fit to any Milky Way arm
5. No abrupt shifts in velocity (of more than 3 km s⁻¹ per 10 pc) within extinction feature
6. Projected aspect ratio $\geq 50:1$.

Figure 3. Distributions of length, radius, aspect ratio, and mass for the 10 bone candidates, based on data from Table 2.

Figure 1. Results of performing a slice extraction along the filamentary extinction feature of our strongest bone candidate, filament 5. The top panel shows a *Spitzer*-GLIMPSE 8 μm image of filament 5, and the red trace indicates the curve (coincident with the extinction feature) along which a *p-v* slice was extracted. The bottom panel shows the *p-v* slice, with the red boxed region indicating the emission corresponding to filament 5.

Figure 2. Position-velocity summary of bone candidates and spiral arm models. Blue background shows ^{12}CO emission from Dame et al. (2001), integrated between $-1^\circ < b < 1^\circ$. Black dots show measurements of BGPS-, HOPS-, MALT90-, and GRS-determined velocities, with particular candidate filaments identified by number (see Table 1 for further identification), or, in the case of Nessie, by name. Lines of varying color show predicted *p-v* spiral arm traces from the literature (see text for references).

Zucker, Battersby & Goodman 2015

Figure 1. Results of performing a slice extraction along the filamentary extinction feature of our strongest bone candidate, filament 5. The bottom panel shows the p - v slice, with the red boxed region indicating the emission corresponding to filament 5.

Figure 2. Position-velocity summary of bone candidates and spiral arm models. Blue background shows ^{12}CO emission from Dame et al. (2001), integrated between $-1^\circ < b < 1^\circ$. Black dots show measurements of BGPS-, HOPS-, MALT90-, and GRS-determined velocities, with particular candidate filaments identified by number (see Table 1 for further identification), or, in the case of Nessie, by name. Lines of varying color show predicted p - v spiral arm traces from the literature (see text for references).

Ragan et al. 2014

Fig. 4. Illustration of the predicted LSR velocities of the Norma (red), Scutum-Centaurus (blue), Sagittarius-Carina (green), and (far) Perseus (yellow) spiral arms as a function of Galactic longitude in the first quadrant taken from Vallée (2008). Each set of two black circles represent the filament sample, taking approximate values of v_{LSR} from the ends of the filaments.

Fig. 1. LSR velocities of the Norma (cyan), Scutum-Centaurus (green) and Sagittarius-Carina (red) spiral arms as function of galactic longitude, as estimated by Reid et al. (2014). The width of the lines, 8 km/s, is equivalent to the spatial width of the filaments from (Reid et al. 2014). For simplicity, we only show the near kinetic distances of the spiral arms. Each line segment represents a GMF, taking the v_{LSR} values from the ends of the filaments. The line segments ended with black circles show GMFs of our sample while those with white stars belong to R14. We also show "Nessie", with a red line ended in red circles.

Abreu-Vicente et al. 2014

Fig. 1. **Top panel:** Spitzer GLIMPSE (Benjamin et al. 2003) and MIPS GAL (Carey et al. 2009) three-color image of the region. Red: $24 \mu\text{m}$, green: $8 \mu\text{m}$, blue: $3.6 \mu\text{m}$. Overlaid contours are the velocity-integrated $^{13}\text{CO}(1-0)$ emission ($-5.0 \text{ km s}^{-1} < v_{\text{lsr}} < 17.4 \text{ km s}^{-1}$) from the Galactic Ring Survey (Jackson et al. 2006). Contours correspond to 3.5, 7.3, 11.2, 15 K km s^{-1} . **Middle panel:** Velocity-integrated $^{13}\text{CO}(1-0)$ map of the region integrated within $-4.95 \text{ km s}^{-1} < v_{\text{lsr}} < 17.36 \text{ km s}^{-1}$. A scale bar of 500 pc is added assuming a kinematic distance of 9.8 kpc. **Bottom panel:** Galactic-latitude-integrated $^{13}\text{CO}(1-0)$ position-velocity map of the region (integrated from $-0.2^\circ < b < 1^\circ$). The clouds G052.24+00.74, G051.69+00.74, the bubble at $l \sim 50^\circ$, and the G52L nebula (Bania et al. 2012) are indicated in the middle and bottom panels. The velocity range we used to produce the $^{13}\text{CO}(1-0)$ integrated intensity map is indicated in the bottom panel as the red shaded region. The emission at $5.23 \text{ km s}^{-1} < v_{\text{lsr}} < 7.2 \text{ km s}^{-1}$ is due to contamination from a different molecular cloud, and some of the emission lies on the red dashed line. This component has a smaller line width $\lesssim 0.5 \text{ km s}^{-1}$, which implies that the contamination comes from a close-by cloud. This is supported by its apparent diffuse morphology. Channel maps of the region are provided in Appendix A.

A 500 pc filamentary gas wisp in the disk of the Milky Way

Guang-Xing Li¹, Friedrich Wyrowski¹, Karl Menten¹, and Arnaud Belloche¹

Max-Planck Institut für Radioastronomie, Auf dem Hügel, 69, 53121 Bonn, Germany

October 14, 2013

ABSTRACT

Star formation occurs in molecular gas. In previous studies, the structure of the molecular gas has been studied in terms of molecular clouds, but has been overlooked beyond the cloud scale. We present an observational study of the molecular gas at $49.5^\circ < l < 52.5^\circ$ and $-5.0 \text{ km s}^{-1} < v_{\text{lsr}} < 17.4 \text{ km s}^{-1}$. The molecular gas is found in the form of a huge ($\gtrsim 500 \text{ pc}$) filamentary gas wisp. This has a large physical extent and a velocity dispersion of $\sim 5 \text{ km s}^{-1}$. The eastern part of the filamentary gas wisp is located $\sim 130 \text{ pc}$ above the Galactic disk (which corresponds to 1.5–4 e-folding scale-heights), and the total mass of the gas wisp is $\gtrsim 1 \times 10^5 M_\odot$. It is composed of two molecular clouds and an expanding bubble. The velocity structure of the gas wisp can be explained as a smooth quiescent component disturbed by the expansion of a bubble. That the length of the gas wisp exceeds by much the thickness of the molecular disk of the Milky Way is consistent with the cloud-formation scenario in which the gas is cold prior to the formation of molecular clouds. Star formation in the filamentary gas wisp occurs at the edge of a bubble (G52L nebula), which is consistent with some models of triggered star formation.

ABSTRACT

The ubiquity of filamentary structure at various scales throughout the Galaxy has triggered a renewed interest in their formation, evolution, and role in star formation. The largest filaments can reach up to Galactic scale as part of the spiral arm structure. However, such large-scale filaments are hard to identify systematically due to limitations in identifying methodology (i.e. as extinction features). We present a new approach to directly search for the largest, coldest, and densest filaments in the Galaxy, making use of sensitive *Herschel* Hi-GAL (*Herschel* Infrared Galactic Plane Survey) data complemented by spectral line cubes. We present a sample of the nine most prominent *Herschel* filaments, including six identified from a pilot search field plus three from outside the field. These filaments measure 37–99 pc long and 0.6–3.0 pc wide with masses $(0.5\text{--}8.3) \times 10^4 M_{\odot}$, and beam-averaged (28 arcsec, or 0.4–0.7 pc) peak H_2 column densities of $(1.7\text{--}9.3) \times 10^{22} \text{ cm}^{-2}$. The bulk of the filaments are relatively cold (17–21 K), while some local clumps have a dust temperature up to 25–47 K. All the filaments are located within $\lesssim 60$ pc from the Galactic mid-plane. Comparing the filaments to a recent spiral arm model incorporating the latest parallax measurements, we find that 7/9 of them reside within arms, but most are close to arm edges. These filaments are comparable in length to the Galactic scaleheight and therefore are not simply part of a grander turbulent cascade.

Key words: catalogues – stars: formation – ISM: clouds – ISM: structure – Galaxy: structure.

Figure 2. Gallery of the selected filaments: column density maps plotted in logarithmic scale in Galactic coordinates. See peak/mean densities for each filament in Table 1. The scale bars denote 10 pc. The red dotted line depicts Galactic plane at the source distance; when accompanied by a red arrow (G11, G24, G26, and G47), it means that the plane is outside of the plotted area, parallel to the red dotted line, at the direction of the arrow. Table 1 lists distance to Galactic plane for each filament.

2014 Simulation

Smith et al. 2014, using AREPO (hydro+chemistry, imposed potential, no B-fields, no local (self-)gravity, no feedback)

Great, but we need synthetic line maps

Filament models: truncated Plummer spheroid (TPS) matches observed N -maps and N -pdfs better than Plummer cylinder, and has similar mean N -profile

from Phil Myers

TPS and TPC models: $p = 2, r_0 = 0.035 \text{ pc}, x_{\text{max}} = 0.175 \text{ pc}, z_{\text{max}} = 2.1 \text{ pc}, M/L = 12.1 M_{\text{Sun}}/\text{pc}$. N -contours: 0.5, 1, 2, 4, 8 10^{21} cm^{-2} .
 TPS model: $n_0 = 6.0 \cdot 10^4 \text{ cm}^{-3}, N_{\text{max}} = 18 \cdot 10^{21} \text{ cm}^{-2}, a_{\text{in}} = 1, a_{\text{out}} = 12$. TPC model: $n_0 = 1.7 \cdot 10^4 \text{ cm}^{-3}, N_{\text{max}} = 5.0 \cdot 10^{21} \text{ cm}^{-2}$.

HI shows huge filaments/combings, aligned with B...

TOPIC

How Long, and Long-lasting, are Filaments?

PROBLEM 1

On what scale(s) does filamentary structure matter, and **when**, in the end-game of star-formation?

PHD 1

For synthetic observations best “matching” molecular line & dust data, determine from whence and when bulk of mass gets to forming cores & stars.

Particular focus on **timing**.

with: Klessen, Glover+; Smith, Fuller+; Caselli, Pineda+; Alves, Lombardi, Hacar, Tafalla+ related to work of 5th-year Harvard grad student H. Chen

EXPERTISE

Profs. A. Goodman, D. Finkbeiner, et al. @ CfA (obs-sim comparison, stats, viz, software, B)

PROBLEM 2

What constraints do “**bones**” offer on:
-the shape of the Galaxy, especially in the vertical direction?
-galaxy evolution models on “short” timescales

PHD 2

Using synthetic observations of models of dense gas & dust structures in MW-like galaxies, measure **statistics** & compare with observations to facilitate estimates re:observed shape, and evolution of “bones.”

with: Smith, Fuller+; Burkert+; Molinari+; Menten 1st-year Harvard grad student C. Zucker working on this!

Now, we are trying *FIVE*, from Hacar et al. 2013, and other clustering algorithms, to study “coherent” core-filament relation.

Filaments offer pre-existing density enhancement.

Collapse is rapid enough that aboriginal filament is not erased, even within a “coherent core.”

In B5, small bound cluster will form c. 40K years from now.

HOT OFF THE PRESS: "FIBERS" WITHIN B5

There are at least three different components in the position-position-velocity space.

And potentially, many more...

Gaussian fitted C180 (2-1) peaks
